The following example illustrates that flexibility provided by the gpG distribution, the adaptive approach offers an improvement over a comparison of the error curves for the adaptive restoration and a 15-dB SNR. The estimated value for least squares. Note that the minimum error point for noise, whereas Fig. 4(b) shows the restored image. Fig. 4(a) shows the blurred image with three degrees of freedom, which is neither gpG nor symmetric. Noise data was scaled such that the resulting corrupted image had a 15-dB SNR. The estimated value for \( \chi^2 \) (Chi squared) with three degrees of freedom, which is neither gpG nor symmetric. Noise data was scaled such that the resulting corrupted image had a 15-dB SNR. The estimated value for \( \chi^2 \) using the method outlined in Section III-A is 1.2. Fig. 4(a) shows the blurred image with \( \chi^2 \) noise, whereas Fig. 4(b) shows the restored image. Fig. 5 presents a comparison of the error curves for the adaptive restoration and least squares. Note that the minimum error point for \( p = 1.2 \) is significantly below that of \( p = 2 \). The encouraging observation here is that even in the presence of noise clearly not well modeled by a gpG distribution, the adaptive approach offers an improvement over methods that implicitly assume a strict Gaussian model.

Another important consideration is whether improvement is possible when the noise distribution is not a member of the gpG family. The following example illustrates that flexibility provided by the shape parameter enables the gpG model to approximate the noise distribution. In this case, the noise was distributed \( \chi^2 \) (Chi squared) with three degrees of freedom, which is neither gpG nor symmetric. Noise data was scaled such that the resulting corrupted image had a 15-dB SNR. The estimated value for \( \chi^2 \) using the method outlined in Section III-A is 1.2. Fig. 4(a) shows the blurred image with \( \chi^2 \) noise, whereas Fig. 4(b) shows the restored image. Fig. 5 presents a comparison of the error curves for the adaptive restoration and least squares. Note that the minimum error point for \( p = 1.2 \) is significantly below that of \( p = 2 \). The encouraging observation here is that even in the presence of noise clearly not well modeled by a gpG distribution, the adaptive approach offers an improvement over methods that implicitly assume a strict Gaussian model.

**Scalable Data Parallel Algorithms for Texture Synthesis Using Gibbs Random Fields**

David A. Bader, Joseph Jajá, and Rama Chellappa

Abstract—This correspondence introduces scalable data parallel algorithms for image processing. Focusing on Gibbs and Markov random field model representation for textures, we present parallel algorithms for texture synthesis, compression, and maximum likelihood parameter estimation, currently implemented on Thinking Machines CM-2 and CM-5. Use of fine-grained, data parallel processing techniques yields real-time algorithms for texture synthesis and compression that are substantially faster than the previously known sequential implementations. Although current implementations are on Connection Machines, the methodology presented here enables machine-independent scalable algorithms for a number of problems in image processing and analysis.

I. INTRODUCTION

Random fields have been successfully used to sample and synthesize textured images [4]-[7], [9]. Texture analysis has applications in image segmentation and classification, biomedical image analysis, and automatic detection of surface defects. Of particular interest are the models that specify the statistical dependence of the gray level at a pixel on those of its neighborhood. There are several well-known algorithms describing the sampling process for generating synthetic textured images and algorithms that yield an estimate of the parameters of the assumed random process given a textured image. Impressive results related to real-world imagery have appeared in the literature [3], [5]-[8]. However, all these algorithms are quite computationally demanding because they typically require on the order of \( O(n^2) \) arithmetic operations per iteration for an image of size

\[ P_r(X = x) = \frac{e^{-C(x)}}{Z} \]

where \( U(x) \) is the energy function, and \( Z = \sum U(x) \), over all \( G \) images; \( G \) being the number of gray levels, and the image is of size \( \sqrt{N} \times \sqrt{N} \). Except in very special circumstances, it is not feasible to compute \( Z \). A relaxation-type algorithm described in [6] simulates a Markov chain through an iterative procedure that readjusts the gray levels at pixel locations during each iteration. This algorithm sequentially initializes the value of each pixel using a uniform distribution. Then a single pixel location is selected at random, and using the conditional distribution that describes the Markov chain, the new gray level at that location is selected, dependent only upon the gray levels of the pixels in its local neighborhood. The sequential algorithm terminates after a given number of iterations.

The sequential algorithm to generate a Gibbs random field described in [6] and [7] is used as a basis for our parallel algorithm. For all the algorithms given in this correspondence, we use a symmetric neighborhood \( N_x \), which is half the size of the standard neighborhood model \( N \). This implies that if the vector \((i, j) \in N_x\) then \((-i, -j) \in N_x\), but only one of \((i, j), (-i, -j)\) is in \( N_x \). Each element of array \( \Theta \) is taken to represent the parameter associated with its corresponding element in \( N_x \). We use the notation \( y_r \) to represent the gray level of the image at pixel location \( r \).

Our Gibbs random field is generated using a simulated annealing type process. For an image with \( G \) gray levels, the probability \( P_r(X = k \text{ neighbors}) \) is binomial with parameter \( \Psi(T) = 1/\Gamma(\tau) \), and number of trials \( G - 1 \). The array \( \{T\} \) is given in the following equation for a first-order model:

\[ T = \alpha + \theta(0,1) [y_r(0,1) + y_r(-1,0)] + \theta(0,0) [y_r(0,1) + y_r(-1,0)] \]

and is a weighted sum of neighboring pixels at each pixel location. Additional examples of \( \{T\} \) for higher order models may be found in [6].

This algorithm is ideal for parallelization. The calculation of \( \{T\} \) requires uniform communication between local processing elements, and all other operations needed in the algorithm are data independent, uniform at each pixel location, scalable, and simple.

B. Gaussian Markov Random Field Sampler

In this section, we consider the class of 2-D noncausal models known as GMRF models, which are described in [3], [5], and [9]. Pixel gray levels have joint Gaussian distributions and correlations controlled by a number of parameters representing the statistical dependence of a pixel value on the pixel values in a symmetric neighborhood. There are two basic schemes for generating a GMRF image model, both of which are discussed in [3]. The iterative GMRF sampler is similar to the Gibbs sampler, but instead of the binomial distribution, we use the continuous Gaussian distribution as the probability function. An efficient parallel implementation is straightforward and similar to that of the Gibbs sampler.

The previous section outlined an algorithm for sampling GMRF textured images using an iterative method. Unfortunately, this algorithm may have to perform hundreds or even thousands of iterations before a stable texture is realized. Next, we present a scheme that makes use of 2-D Fourier transforms and does not need to iterate. The direct GMRF sampler algorithm is realized from [3] as follows. We use the following scheme to reconstruct a texture from its parameters $\theta$ and a neighborhood $\Omega$:

$$ f_\sigma = \text{Col} \left[ 1, \lambda_1, \lambda_1^2, \cdots, \lambda_1^{M-1} \right] \text{, an } M^2\text{-vector,} $$

$$ t_\sigma = \text{Col} \left[ 1, \lambda_1, \lambda_2, \cdots, \lambda_2^{M-1} \right] \text{, an } M\text{-vector,} $$

and $\lambda_1 = \exp \left( \sqrt{-1} \frac{2 \pi \nu}{M} \right)$.  

III. PARAMETER ESTIMATION FOR GMRF TEXTURES

Given a real textured image, we wish to determine the parameters of a GMRF model that could be used to reconstruct the original texture through the samplers given in the previous section.

This section develops parallel algorithms for estimating the parameters of a GMRF texture. The methods of least squares (LSE) and of maximum likelihood (MLE), both described in [3], are used. We present efficient parallel algorithms to implement both methods. The MLE performs better than the LSE. This can be seen visually by comparing the textures synthesized from the LSE and MLE parameters, or by noting that the asymptotic variance of the MLE is lower than the LSE [2], [10].

A. Least Squares Estimate of Parameters

The least squares estimate detailed in [3] assumes that the observations of the GMRF image $\{y_\sigma\}$ obey the model

$$ y_\sigma = \sum_{\mathcal{N}_\sigma} \Theta_\sigma y_{\sigma+r} + e_\sigma, \quad \forall \sigma \in \Omega \quad (7) $$

where $\{e_\sigma\}$ is a zero-mean correlated noise sequence with variance $\nu$ and correlation with the following structure:

$$ E(e_\sigma e_{\sigma'}) = -\Theta_\sigma \nu, \quad \text{if } (\sigma - \sigma') \in \mathcal{N}_\sigma, $$

$$ 0, \quad \text{otherwise.} $$

Then, for $g_\sigma = \text{Col} \left[ y_{\sigma+r}, y_{\sigma-r}, r' \in \mathcal{N}_\sigma \right]$, the LSE are

$$ \Theta^* = \left( \sum_{\Omega} g_\sigma g_\sigma^T \right)^{-1} \left( \sum_{\Omega} g_\sigma y_\sigma \right) $$

$$ \nu^* = \frac{1}{M^2} \sum_{\Omega} (y_\sigma - \Theta^* g_\sigma)^2 $$

where $\Omega$ is the complete set of $M^2$ pixels, and toroidal wrap-around is assumed.

B. Maximum Likelihood Estimate of Parameters

We introduce the following approach as an improved method for estimating GMRF parameters of textured images. The method of maximum likelihood gives a better estimate of the texture parameters since the asymptotic variance of the LSE is lower than that of the LSE. We also show a much faster algorithm for optimizing the joint probability density function, which is an extension of the Newton–Raphson method and is also highly parallelizable.

Assuming a toroidal lattice representation for the image $\{y_\sigma\}$ and Gaussian structure for noise sequence $\{e_\sigma\}$, the joint probability density function is the following:

$$ p(y | \theta, \nu) = \frac{1}{(2\pi \nu)^{\frac{M^2}{2}}} \prod_{\sigma \in \Omega} \left( 1 - 2 \sum_{r \in \mathcal{N}_\sigma} [\Theta_\sigma \Phi_\sigma | (\sigma)] \right) \cdot \exp \left( -\frac{1}{2\nu} \left( C(\theta) - \sum_{r \in \mathcal{N}_\sigma} [\Theta_\sigma C(\sigma)] \right) \right). $$

Fig. 4. Isotropic inhibition texture using Gibbs sampler (Texture 9b from [6]).
In (10), \( C(r_i) \) is the sample correlation estimate at lag \( r_i \). As described in [2] and [3], the log-likelihood function can be maximized: (note that \( F(\Theta, \nu) = \log p(y|\Theta, \nu) \))

\[
F(\Theta, \nu) = -\frac{M^2}{2} \log 2\pi \nu + \frac{1}{2} \sum_{r_i \in \Omega} \left( \log \left( 1 - 2 \sum_{r_j \in \mathcal{N}_r} |\Theta_{r_i, r_j}(\sigma)| \right) \right)
- \frac{1}{2\nu} \sum_{r_i \in \Omega} \left( g(\sigma)^2 - g(\sigma) \right) \sum_{r_j \in \mathcal{N}_r} \left( \Theta_{r_i, r_j} g(\sigma + r_i + r_j) + g(\sigma - r_i) \right).
\]

(11)

For a square image, \( \Phi_{r_i}(\sigma) \) is given as follows:

\[
\Phi_{r_i}(\sigma) = \cos \left( \frac{2\pi}{M} \sigma^T r_i \right).
\]

(12)

This nonlinear function \( F \) is maximized by using an extension of the Newton–Raphson method. This new method first generates a search direction \( \nu^k \) by solving the system

\[

\nabla^2 F(\Theta_k)|_{r_i+1 \times (r_i+1)} [\nu^k]|_{r_i+1 \times 1} = -[\nabla F(\Theta_k)|_{r_i+1 \times 1}].
\]

(13)

Note that this method works well when \( \nabla^2 F(\Theta_k) \) is a symmetric, positive-definite Hessian matrix. We then maximize the step in the search direction, yielding an approximation to \( \lambda_k \) that attains the local maximum of \( F(\Theta_k + \lambda \nu) \) and also satisfies the constraints that each of the \( M^2 \) values in the logarithm term for \( F \) is positive. Finally, an optimality test is performed. We set \( \Theta_k+1 = \Theta_k + \lambda \nu \), and if \( \Theta_k+1 \) is sufficiently close to \( \Theta_k \), the procedure terminates. We give the first and second derivatives of \( F \) with respect to \( \Theta_k \) and \( \nu \) in [1].

For a rapid convergence of the Newton–Raphson method, it must be initialized with a good estimate of parameters close to the global maximum. We use the least squares estimate given in Section III-A as \( \Theta_0 \), the starting value of the parameters.

**IV. CONCLUSIONS**

We have presented efficient data parallel algorithms for texture analysis and synthesis based on Gibbs or Markov random field models. A complete software package running on the Connection Machine model CM-2 and the Connection Machine model CM-5 implementing these algorithms is available for distribution to interested parties. Please see http://www.umiacs.umd.edu/~dbader for additional information. The experimental data strongly support the analysis concerning the scalability of our algorithms. The same type of algorithms can be used to handle other image processing algorithms such as image estimation [8], [9], texture segmentation [5], and integration of early vision modules. We are currently examining several of these extensions.
The parameters for the 256 × 256 image of tree bark texture in Fig. 5 are given in Table II.

Linear Filtering of Images Based on Properties of Vision

V. Ralph Algazi, Gary E. Ford, and Hong Chen

Abstract—The design of linear image filters based on properties of human visual perception has been shown to require the minimization of criterion functions in both the spatial and frequency domains. In this correspondence, we extend this approach to continuous filters of infinite support. For lowpass filters, this leads to the concept of an ideal lowpass image filter that provides a response that is superior perceptually to that of the classical ideal lowpass filter.

I. INTRODUCTION

The use of hard cutoff (ideal) lowpass filters in the suppression of additive noise is known to produce ripples in the response to sharp edges. For high contrast edges, human visual perception fairly simply determines acceptable filter behavior. Ripples in the filter response are visually masked by the edge, so that the contrast sensitivity of the visual system decreases at sharp transitions in image intensity and increases somewhat exponentially as a function of the spatial distance from the transition.

Algorithmic procedures using properties of human vision have been described for over 20 years [1]. The development of adaptive methods of image enhancement and restoration, based on the use of a masking function, measure spatial detail to determine visual masking [2], [3]. In active regions of the image, visual masking is high, relative noise visibility is low, and the filter applied is allowed to pass more noise until the subjective visibility is equal to that in flat areas.

Whether the filter is adaptive or not, the design of the linear filter to be applied is a critical issue. Hentea and Algazi [4] have demonstrated that the first perceptible image distortions due to linear filtering occur at the major edges and thus, worst case design for visual appearance should be based on edge response. They developed a filter design approach based on the minimization of a weighted sum of squared-error criterion functions in both the spatial and frequency domains. In the spatial domain, the weighting is by a visibility function, representing the relative visibility of spatial details as a monotonically increasing function of the distance from an edge. This visibility function, determined experimentally from the visibility of a short line positioned parallel to an edge, was also found experimentally to predict satisfactorily the visibility of ripples due to linear filters [4].

In the following, we extend the work of Hentea and Algazi by considering the design and properties of one-dimensional continuous filters of infinite support (two-dimensional filters are generated by 1D to 2D transformations). We obtain a new formal result on the lowpass filter of infinite support that is optimal for images. It establishes the limiting performance that digital filters of finite complexity can only approximate.

II. DESIGN OF ONE-DIMENSIONAL FILTERS FOR IMAGES

The basic tradeoff in the design approach of Algazi and Hentea [4] is maintaining image quality while reducing unwanted artifacts or noise. The image quality is measured by spatial domain criterion function for the visibility of ripples in the vicinity of edges

\[ I_1 = \int_{-\infty}^{\infty} (u'(x))^2 \cdot \Gamma(x) dx \]

where \( u(x) \) is a unit step input producing the filter response \( u'(x) = u(x) \ast h(x) \), where \( h(x) \) is the point spread function of the filter, \( \ast \) denotes convolution and \( u'(x) \) is a spatial weighting function, chosen to be the visibility function

\[ w_1(x) = 1 - u'(x) \]

The frequency domain criterion function for the reduction of unwanted artifacts and noise is

\[ I_2 = \int_{-\infty}^{\infty} W_2^2(f) \cdot |H(f) - H_a(f)|^2 df \]

where \( H_a(f) \) is the desired filter frequency response and \( W_2^2(f) \) is the frequency-domain weighting function. Hentea and Algazi minimized \( I_1 \) under a constraint on \( I_2 \), but we now minimize the equivalent criterion \( J(\alpha) = \alpha I_1 + (1 - \alpha) I_2 \) where \( \alpha \) controls the relative weights of the two criteria, with \( 0 \leq \alpha \leq 1 \).

To develop the optimality condition, (1) is expressed in the frequency domain using Parseval’s relation, the transform of a zero-mean step is used, and calculus of variations is applied to the criterion
